ABSTRACT

This paper considers the trade-off, for cointegration tests, between dimension and power: that is, we compare the power performance of test-statistics which are dimension-invariant but impose common-factor restrictions with tests which are not dimension free but do not impose those restrictions. As a byproduct of the analysis, we consider cases where the t-ratio form of the tests have better power properties than the coefficient form, in spite of the latter diverging at rate $O(T)$ and the former at $O(T^{1/2})$, under the alternative hypothesis of cointegration.

(*) We are grateful to Luis Alvarez, Manuel Arellano, Peter Boswijk, Jesús Gonzalo, Niels Haldrup, David Hendry, Svend Hylleberg, Soren Johansen, James MacKinnon, Enrique Sentana, Gregor Smith. two anonymous referees and participants in seminars at the University of Oxford, University of Barcelona, CEMFI and ESEM'93 Uppsala for helpful discussions and to Araceli Requerey for her skill in typing the manuscript. The first author also wishes to thank the Dpt. of Economics at Queen's for their hospitality while a revised version of this paper was being written. The usual caveat applies.
1. INTRODUCTION

This paper compares the performance of a number of cointegration tests. The tests considered fall into two classes. The first consists of dimension-invariant tests, as recently proposed by Hansen (1990), based on the Cochrane-Orcutt estimation procedure (henceforth denoted as C-O test). The advantage of these tests is that they converge to the Dickey-Fuller distribution regardless of the number of variables in the cointegrating regression. The second class consists of tests based on the estimated error-correction coefficient in the ECM representation of the model, as proposed by Banerjee et al. (1986) and Boswijk (1991) (henceforth denoted as ECM test). In comparing both types of tests, we extend the argument made in Kremers et al. (1992), about imposing potentially invalid common-factor restrictions in residual based cointegration tests with known cointegrating vectors, to the case where cointegrating vectors have to be estimated, and argue that the dimension-invariant class of tests may suffer from the same problem. Consequently, if these restrictions are not satisfied the tests may have poor power properties.

Furthermore, as a byproduct of the analysis under the alternative hypothesis of cointegration, we show that cointegration tests based upon the t-ratio form may sometimes have better power properties than tests based upon the estimated coefficient itself. This is an interesting result, since as shown by Phillips and Ouliaris (1990), under the alternative hypothesis, the former test has non-centrality which grows at rate $T^{1/2}$ while the non-centrality parameter of the latter test diverges at rate $T$. However, we show that, for finite samples, as a local result,
the t-form may be superior.

To examine the asymptotic and finite-sample properties of the various test procedures, we use a very simple, but illustrative, data generating process (DGP), and later show that the reason for the lack of power of the dimension-invariant tests may remain in more general cases.

The basic framework of reference is that of single equation conditional error correction models where OLS is an asymptotically efficient estimation procedure. For expository purposes, in most of the paper we use the simplifying assumption that the regressors are strongly exogenous for the parameters of interest. Later on in the analysis we generalise the results to the more realistic case where the regressors are only weakly exogenous but the use of OLS is still asymptotically optimal. We show that the ECM test in that case is not similar, i.e. depends on nuisance parameters. To overcome that problem, a "modified" ECM test is suggested which turns out to be asymptotically similar.

The rest of the paper is organised as follows. Section 2 presents the data generation process (DGP) of interest, briefly describes both the C-O and the ECM test procedures and compares their asymptotic distributions under the null hypothesis of non-cointegration. Section 3 gives the corresponding limiting distributions under the alternative hypothesis of cointegration, using both a fixed alternative and a near non-cointegrated alternative. Section 4 provides Monte-Carlo finite-sample evidence about the illustrative DGP. Section 5 considers generalisations to more realistic cases. Concluding remarks are given in section 6.

In common with most of the literature in this field, we follow some notational conventions. The symbol "*" denotes weak
convergence of probability measures; \( \rightarrow \) denotes convergence in probability; \( = \) denotes equality in distribution; \( \mathcal{BM}(\Omega) \) refers to a Brownian motion with long-run covariance matrix \( \Omega \). Arguments of functionals on the space \([0,1]\) are frequently suppressed and integrals with respect to Lebesgue measure on the space \([0,1]\) such as \( \int_0^1 B^2(r) dr \) are written as \( \int B^2 \) to reduce notation. Emboldened symbols represent vectors or matrices of variables. Proofs of important results are relegated to the appendix.

2. A SIMPLE DGP AND THE C-O AND ECM TEST STATISTICS

By using a simple DGP, based upon a multivariate dynamic process, this section describes the C-O and ECM testing procedures.

This bivariate DGP has been used elsewhere [c.f. Davidson et al. (1978), Banerjee et al. (1986) and Kremers et al. (1992)] and has the form:

\[
\begin{align*}
\Delta y_t &= \alpha' \Delta x_t + \beta(y_{t-1} - \lambda' x_{t-1}) + e_t \\
\Delta x_t &= u_t
\end{align*}
\]

where \( \Delta y_t = y_t - y_{t-1}, \Delta x_t = x_t - x_{t-1} \), and

\[
1 \begin{bmatrix} e_t \\ u_t \end{bmatrix} \sim \text{IN} \left( \begin{bmatrix} 0 \\ 0 \end{bmatrix}, \begin{bmatrix} \sigma^2 & 0 \\ 0 & \Sigma_u \end{bmatrix} \right) \equiv \text{N}(0, \Sigma)
\]

and \( \alpha, \lambda \) and \( x_t \) are \((k \times 1)\) vectors of parameters and explanatory variables. With this set-up, the partial sum processes

\[
S_T(r) = T^{-1/2} \sum_{t=1}^{\lfloor T r \rfloor} (e_t' u_t')
\]

satisfy the multivariate invariance principles [c.f. Phillips and Durlauf (1986)].
\[ S_t(r) = \Sigma^{1/2} B(r) = BM(\Omega) \]

where \( B(r) = (B_c(r), B_u(r))' \) is a \((k+1)\) vector standard Brownian motion, i.e. \( BM(1) \).

We further assume that \(-2 < \beta \leq 0\). In this DGP, \( y_t \) and \( x_t \) are cointegrated when \(-2 < \beta < 0\), while they are not cointegrated when \( \beta = 0 \). Thus, tests of cointegration must rely upon some estimate of the parameter \( \beta \). Under the simplifying assumption that \( x_t \) is strongly exogenous (c.f. Hendry and Richard (1982)) for the parameters of the conditional model (1), non-linear least squares (NLS) can be applied to (1) yielding consistent estimates of \( \alpha, \beta \) and \( \lambda \). Either the coefficient estimate \( \hat{\beta} \) or the \( t \)-ratio based upon \( \hat{\beta} \) can be used to test the null hypothesis that \( y_t \) and \( x_t \) are cointegrated with cointegrating vector \((1, -\lambda')\). However, it is well known that the asymptotic distributions of these test-statistics shift away from the origin as the dimensionality of the vector \( x_t \) increases (see, for example, Banerjee and Hendry (1992) and MacKinnon (1994)). Thus, larger test statistics are needed for rejection, reflecting the fact that this class of test-statistics is not dimension-invariant. This has often been called the "curse of dimensionality".

Hansen's C-O procedure corrects for this problem by using an iterative estimation variant of the Engle and Granger (1987) procedure. According to the C-O procedure [c.f. Cochrane and Orcutt (1949)], the iterated method is equivalent to estimating the parameters of the following model by NLS

\[ \Delta y_t - \lambda' \Delta x_t = \beta' [y_{t-1} - \lambda' x_{t-1}] + \epsilon_t \quad (3) \]

4
where substitution of (2) into (1) implies that \( e_t = (\alpha - \lambda)' u_t + \epsilon_t \).

Denoting the NLS estimators of \( \lambda \) and \( \beta \) in (3) by \( \hat{\lambda}_{co} \) and \( \hat{\beta}_{co} \), respectively, Hansen (1990, Theorem 2) proves the following result.

**Proposition 1.** For DGP (1)-(2), under the null hypothesis of no-cointegration \( (\beta=0) \)

\[
T^{1/2} (\hat{\lambda}_{co} - \alpha) \Rightarrow N(0, \sigma_{T}^2 \Sigma_u^{-1})
\]

\[
T \hat{\beta}_{co} \Rightarrow \int B \epsilon \ dn / \int B \epsilon
\]

and

\[
t_{co} \Rightarrow \int B \epsilon \ dn / (\int B \epsilon)^{1/2}
\]

where \( t_{co} \) is the t-ratio defined as

\[
t_{co} = (\sigma_{T}^{-2} \int z_{co-1}^- z_{co-1}^-' \int z_{co}^- z_{co}^-' )^{1/2} \hat{\beta}_{co} ; \sigma_{T}^2 = T^{-1} \hat{\epsilon} T
\]

with \( \hat{z}_{co} = y_t - \hat{\lambda}' x_t \) and \( \hat{z}_{co} \) is a \((T \times 1)\) vector of observations on \( \hat{z}_{co} \).

The previous results show that both the C-U coefficient and t-ratio tests have the limiting Dickey-Fuller distributions. Note also that these tests are asymptotically similar, i.e. invariant to the nuisance parameters of the DGP \( (\alpha, \sigma_{T}^2, \Sigma_u) \) under the null hypothesis.

Although the previous test statistics are dimension-invariant, i.e. their distributions are independent of the dimension of the vector \( x_t \), it is important to note that the equation (3), as compared to equation (1), ignores part of the
information contained in $\Delta x_t$. Equivalently, (3) imposes the restriction that $\alpha=\lambda$, i.e., a common-factor restriction. The transformation of (1) to (3) provides several interesting insights. First, (1) and (3) are equivalent representations of the DGP, given the relationship between $\epsilon_t$ and $e_t$ noted above, but the two errors are not equal unless $\alpha=\lambda$. Second, the same condition ($\alpha=\lambda$) is required for the common-factor restriction to be valid. This follows from noting that

$$[1-(1+\beta)L]y_t = [a-(a+\lambda\beta)L]'x_t + \epsilon_t \quad (4)$$

where $L$ is the lag operator ($\Delta = 1-L$).

Interestingly, in this case, even if the common-factor restriction is invalid, $e_t$ remains white noise, although not an innovation with respect to lagged $x_t$ and $y_t$.

The ECM test statistic for cointegration, as suggested by Banerjee et al. (1986) and Boswijk (1991), can be based upon estimating (1) by NLS and testing $H_0: \beta=0$. Alternatively, Banerjee et al. (1993), using the results of Kiviet and Phillips (1992), show that a parameter free distribution for the estimator of $\beta$ can be achieved if $x_{t-1}$ is added to (1), setting $\lambda=0$ without loss of generality. This is so, since, under the alternative hypothesis, the true cointegrating slope $\lambda$ is implicitly estimated when $x_{t-1}$ is included as an additional regressor under the assumption of strong (weak) exogeneity of $x_t$ with respect to $\beta$ and $\lambda$. Therefore, according to this procedure, $\beta$ is estimated by OLS from the unrestricted dynamic model

$$\Delta y_t = \alpha' \Delta x_t + \beta y_{t-1} + \theta' x_{t-1} + \epsilon_t = \alpha' \Delta x_t + \pi' w_{t-1} + \epsilon_t \quad (1')$$

6
where \( w'_t = (y'_t, x'_t)' \) and \( \pi' = (\beta, \theta') \).

Since \( \beta(1, -\lambda') = \pi' \), then the non-cointegration restriction \( \beta = 0 \) implies \( \pi = 0 \) and so the ECM test can be based on the significance of the OLS estimator of \( \beta \), denoted by \( \hat{\beta} \) in (1)'. Thus letting \( y \) and \( \Delta y \) be \((T \times 1)\) vectors of observations on \( y_t \) and \( \Delta y_t \), the ECM estimator, is defined by

\[
\hat{\beta} = (y'_{-1} M y_{-1})^{-1} y_{-1} M \Delta y
\]  

(5)

where \( M = I - V'(V'V)^{-1} V' \) and \( V \) is a \((T \times 2)\) matrix of observations on \( v_t = (\Delta x'_t, x'_{t-1})' \). The following proposition holds.

Proposition 2. For DGP(1)-(2), under the null hypothesis of no cointegration (\( \beta = 0 \))

\[
T_t = [(B^2 - (B B')' (B B')^{-1} (B B')^{-1})^2 (B B - (B B')' (B B')^{-1} (B B')] \\
\leq u u \begin{pmatrix} u & \epsilon \\ \epsilon & u \end{pmatrix} u u \\
= [\bar{B}^2]^{-1} \bar{B} dB \\
\epsilon \begin{pmatrix} \bar{B} \epsilon \\ \epsilon \end{pmatrix}
\]

with \( \bar{B} = B - (B B')' (B B')^{-1} B \\
\leq u u \begin{pmatrix} u & \epsilon \\ \epsilon & u \end{pmatrix} u u \\
\bar{B} dB \\
\epsilon \begin{pmatrix} \bar{B} \epsilon \\ \epsilon \end{pmatrix}
\]

and

\[
t_t = [\bar{B}^2 - (B B')' (B B')^{-1} (B B')^{-1} [B B - (B B')' (B B')^{-1} B dB] \\
\leq u u \begin{pmatrix} u & \epsilon \\ \epsilon & u \end{pmatrix} u u \\
= [\bar{B}^2]^{-1} / 2 \bar{B} dB \\
\epsilon \begin{pmatrix} \bar{B} \epsilon \\ \epsilon \end{pmatrix}
\]

where \( t_t \) is the \( t \)-ratio defined as

\[
t_t = \frac{\hat{\beta} - \beta}{\sigma_\epsilon^{-1 / 2} y'_{-1} M y_{-1}^{-1 / 2} T \hat{\beta}} = \frac{T \hat{\beta}}{\theta_\epsilon^{-1 / 2}}
\]

Note that \( \bar{B} \) is the residual from the continuous time
regression of $B_c$ on $B_u$. Thus the above distributions depend upon
the number of elements (k) in $x_t$, as reflected by the presence of
$B_u$ in $B_c$, implying that the corresponding test-statistics are not
dimension-invariant.

Remark. As a curiosity, it can be noted from the previous limiting
distributions that there is a transformation of $T_{\beta E}$ or $t_E$ which
has the Dickey-Fuller distribution and is also dimension-free. We
will denote such estimator as EDF estimator (ECM cum Dickey-Fuller
distribution). It is immediate to see that $\beta_E$ in (5) is identical
to

$$\hat{\beta}_E = (z_{E-1} z_{E-1})^{-1} z_{E-1} M \Delta z_E$$  \hspace{1cm} (6)

where $\hat{z}_{E_t} = y - \hat{\alpha}_E x_t$ and $\hat{z}_E$ is a (Tx1) vector of observations on $\hat{z}_{E_t}$, where $\hat{\alpha}_E$ is the OLS estimator of $\alpha$ in (1'). Now, since the
projection matrix $M$ anihilates both $x_{-1}$ and $\Delta x$, tests based upon
the following estimator

$$\hat{\beta}_{EDF} = (z_{E-1} z_{E-1})^{-1} z_{E-1} \Delta z_E$$  \hspace{1cm} (7)

such as $T_{\beta EDF}$ or the t-ratio, have the Dickey-Fuller asymptotic
distributions. Thus, this is the only test which does not impose
common-factor restrictions and is dimension invariant. However, in
a sense, this is the free-lunch case, i.e. it seems to buy
dimension-invariance at zero cost, and should not be expected to
exist to play a useful role. This is indeed what happens. The EDF
test-statistics test for the stationarity of $\hat{z}_{E_t}$ which is an
inconsistent estimator of the true ECM term, $y_t - \lambda' x_t$, because $\hat{\alpha}_E \neq \alpha$
and not to $\lambda$, under the alternative hypothesis of cointegration.
Hence, the EDF test has zero power under fixed alternatives of cointegration and we do not discuss this test further.\(^1\)

3. DISTRIBUTION OF THE STATISTICS UNDER THE ALTERNATIVE HYPOTHESIS OF COINTEGRATION

The alternative hypothesis is that of cointegration which, for (1)-(2), is given by \(-2<\beta<0\). Because the error-correction term in (1) is stationary under the alternative hypothesis, distributional results from conventional central limit theorems, instead of functional central limit theorems, apply for fixed alternatives. In contrast, under a suitable sequence of local alternatives, the non-conventional asymptotic theory developed by Phillips (1987b, 1988) for near-integrated time series can be applied to sharpen the results on the relative asymptotic power functions for the C-O and ECM tests. In order to provide some intuition for the results obtained under near-no cointegration we first discuss briefly the fixed alternative case.

The main result here is that the ECM test tends to have higher power than the C-O test when \(\text{var}(e_t)\) is large relative to \(\text{var}(e_t')\). The intuition behind these results is as follows. The ECM regression conditions on \(\Delta x_t', x_{t-1}\) and \(y_{t-1}'\), whereas the C-O regression conditions on the three sets of variables subject to restrictions. This results in a loss of potentially valuable information. Consider again the alternative representations of equation (1):

\[
\Delta y_t = \alpha' \Delta x_t + \beta(y_{t-1}' - \lambda' x_{t-1}') + e_t = \lambda' \Delta x_t + \beta(y_{t-1}' - \lambda' x_{t-1}') + e_t
\]

As an extreme example, let \(e_t \rightarrow 0\) but \(\alpha \neq \lambda\) and \((\alpha-\lambda)' \Sigma (\alpha-\lambda)\) is
"substantial". In that case, the ECM regression has a near perfect fit with \( \alpha, \beta \) and \( \lambda \) being estimated with near exact precision, and the t-ratio for \( \hat{\beta}_c \) is (arbitrarily) large. However, since the variance of \( e_t \) is

\[
\sigma_e^2 = (\alpha - \lambda)' \Sigma_u (\alpha - \lambda) + \sigma_c^2
\]

the estimates of \( \lambda \) and \( \beta \) in the C-O procedure will be much more imprecise, affecting the power of the test based upon \( \hat{\beta}_c \).

3.1 Distributions under a Local Alternative Hypothesis

To formalise the intuition for the case of local alternatives, we use the distribution theory for local alternatives discussed in Phillips (1987b, 1988) *inter alia*. These non-central distributions help in the analysis of the local asymptotic power properties of the various tests and, as a limiting case, they allow us to obtain the distribution under fixed alternatives. A similar method was used by Kremers *et al.* (1992) for the case where the potential cointegrating vector was assumed to be known and did not need to be estimated. Consider the following parameterisation

\[
\beta = 1 - \exp(c/T) = -c/T
\]

In (8), \( c \) is a fixed scalar. We call time series that are generated by (1)-(2), with \( \beta \) as in (8), near-no cointegrated, following the terminology introduced by Phillips (1987b) for univariate processes. The scalar \( c \) represents a non-centrality parameter which may be used to measure deviations from the null
hypothesis $H_0: \beta = 0$. When $c > 0$, (8) represents a local alternative to $H_0$, so that the rate of approach is controlled and the effect of the alternative hypothesis on the limiting distribution of the statistics, based on the DGP (1)-(2)-(8), is directly measurable in terms of the non-centrality parameter $c$.

To proceed to the analysis of local power, use is made of the following diffusion process

$$K(r) = \int_{0}^{r} \exp[c(r-s)]dB(s) \equiv B(r) + c \int_{0}^{r} \exp[c(r-s)]Bds \quad (9)$$

associated with the standardised disturbances $e$, $u$ and $e$, denoted as $K_e$, $K_u$ and $K_e$, respectively. Note that if $c = 0$ then $K = B$.

Using (9) it is possible to show the following result:

**Proposition 3.** For DGP (1)-(2) and (8), under the alternative hypothesis of near-no cointegration ($c > 0$)

$$\hat{\Gamma}_c = \left\{ \sigma^2 e e K^2 - 2\sigma (\alpha - \lambda)' e e K + (\alpha - \lambda)' e u e + (\alpha - \lambda)' e u u e \right\}^{-1}$$

$$\left\{ -c \left[ \sigma^2 e e K^2 - \sigma (\alpha - \lambda)' e e K \right] + \sigma e e K dB - \sigma (\alpha - \lambda)' e e K dB \right\} \equiv \phi_c$$

$$\hat{\Gamma}_e = -c + \left\{ \sigma^2 e e (\sigma K)' e e (\sigma K)^{-1} e e \right\}^{-1}$$

$$\sigma e e \left\{ \sigma K dB - e e (\sigma K)^{-1} e e dB \right\} \equiv \phi_e$$

whereas in the case of the t-ratios,
$$t_{co} = \left\{ \sigma_e^{-2} \left[ \begin{array}{c} \sigma_e^{-2} \left( \Sigma_u \right) + (\alpha-\lambda) \left( \Sigma_u \right) \right] \right\}^{1/2} \phi_{co}$$

$$t_{\epsilon} = \left\{ \sigma_e^{-2} \left[ \begin{array}{c} \sigma_e^{-2} \left( \Sigma_u \right) \right] \right\}^{1/2} \phi_{\epsilon}$$

Since $\sigma_e K_e = (\alpha-\lambda) \Sigma_u^{1/2} K_u e$, note that, when $c=0$, the non-centrality parameters of the three statistics are zero, $K=B$ and the distributions under the null in Propositions 1 & 2 are recovered, i.e. power equals size.

Although the comparison of the asymptotic distributions under the alternative local hypothesis is cumbersome, given the complexity of the Wiener functional derived above, we expect that the power of the $C-O$ test will be higher than the power of the ECM test under those assumptions wherein the "curse of dimensionality" is strongest, i.e. when the common factor restrictions are valid and the number of regressors is large. However, when these restrictions do not hold, the relative ranking in power may be totally altered. To illustrate this case, let us simplify the analysis by assuming that there is a single regressor, that is $k=1$. Then, given the existing relationship between the disturbances $e_t$, $\epsilon_t$ and $u_t$:

$$e_t = (\alpha-\lambda) u_t + \epsilon_t$$

we will define a "signal-to-noise" ratio $q=(\alpha-\lambda)s$ with $s=\sigma_u/\sigma_e$ corresponding to the ratio of the (square root of the)variance of $(\alpha-\lambda)\Delta x_t$ relative to $\epsilon_t$. This ratio will play a prominent role in the analysis since, as $q \rightarrow 0$, it allows for "small-$\sigma$" approximations, i.e. $s^{-1} \rightarrow 0$; cf. Kadane (1970, 1971). Making use of
these results, the following proposition holds.

Proposition 4. For DGP (1)-(2) and (8), when k=l, under the alternative hypothesis of near-no cointegration (c > 0):

\[
\hat{\theta}_{co} \Rightarrow -c \left[ \int (K - B)^2 \right]^{-1/2} \int (K e - B e) + o_p(q^{-1})
\]

\[
\hat{\theta}_{E} \Rightarrow -c + o_p(q^{-1})
\]

whereas in the case of the t-ratios,

\[
t_{co} \Rightarrow -c \left[ \int (K - B)^2 \right]^{-1/2} \int (K e - B e) + o_p(q^{-1})
\]

\[
t_{E} \Rightarrow -c(1 + q^2)^{1/2} \left[ \int K^2 - (\int K B)^2 / (\int B^2) \right]^{1/2} + \left[ \int K^2 - (\int K B)^2 / (\int B^2) \right]^{1/2}
\]

\[
[\int K dB - (\int K B)(\int B dB) / (\int B^2)] + o_p(q^{-1})
\]

Various interesting properties arise from Proposition 4. In what follows it will be convenient to divide the discussion between those properties pertaining to the coefficient-test statistics and those relating to the t-ratios.

a) Coefficient Test-Statistics

First, asymptotically as q → 0, i.e. α ≠ λ and s → 0ω, the non-centrality parameter in the C-O test has a stochastic slope given by zero whereas the ECM test has a slope equal to (minus) unity, i.e. there is a degenerate distribution centred on (-c). The intuition behind this result is that the variance of the denominator in the distribution of \( \hat{\theta}_{co} \) tends to overcome the variability of the numerator, leading to low power in the C-O test. Hence, the ECM test will tend to be more powerful than the
C-O test when q is sizeable, for a given sample size.

Second, and most importantly, from Proposition 2, since the limiting distribution of $\hat{T}_E$ is independent of q under the null hypothesis, and degenerates around $(-c)$ under the local alternative, for small values of c, the lower 5% tail of the distribution under the null will tend to be to the left of $(-c)$. Therefore, we should also observe very low power of the test based on the ECM coefficient, although higher than that pertaining to the C-O test as q gets larger. Notice that this problem does not arise with the t-ratio version of the ECM test, as will be seen below. For this reason, the tests based upon the t-ratios might be preferable to those based directly on the scaled coefficients.

b) t-ratio Test-Statistics

In this case the limiting distribution of the ECM test has a stochastic slope which depends upon q and does not degenerate around a single value as in the case of the tests based on the coefficient. In the case of the C-O test-statistic, using arguments similar to those employed previously, Proposition 4 shows that the limiting distribution does not depend on q. Thus when q is sizeable, its power will be lower than that of the ECM test, tending towards zero even though the limiting distribution under the local alternative tends to be less skewed to the left than that under the null hypothesis.

3.2 Distributions under a Fixed Alternative Hypothesis

For the case of the fixed alternative ($c^\omega$ and $T^\omega$), the deviation from equilibrium ($y-\lambda'x$) is stationary and the limiting distributions are as follows:
Proposition 5. For DGP (1)-(2), under a fixed alternative hypothesis ($\beta<0$), with $q^2=(\alpha-\lambda)'\Sigma_u(\alpha-\lambda)/\sigma^2_\varepsilon$

\[
\begin{align*}
\hat{T}_\beta_{co} &= T^{1/2}N(0,1-(1+\beta)^2) + T\beta = O_p(T) \\
\bar{t}_c &= N(0,1) + [T/(1-(1+\beta)^2)]^{1/2} = O_p(T^{1/2}) \\
\hat{T}_\beta_{E} &= T^{1/2}N(0,(1-(1+\beta)^2)/1+q^2) + T\beta = O_p(T) \\
\bar{t}_E &= N(0,1) + [T(1+q^2)/(1-(1+\beta)^2)]^{1/2} = O_p(T^{1/2})
\end{align*}
\]

Remark. Note that, for given $q$, the coefficient tests are $O_p(T)$ whilst the $t$-ratio tests are $O_p(T^{1/2})$, as shown by Phillips and Ouliaris (1990, Theorem 5.1). However, notice that the non-centrality parameters of the $t$-ratio test will be larger than that of the coefficient test if $T<1/(1+\beta)^2$ (in the C-O case) and $T<(1+q^2)/[1-(1+\beta)^2]$ (in the ECM case). In terms of power itself, it is easy to see that, for both classes of tests, the power of the $t$-test will be larger than that of the coefficient test if $(1+\beta)^2<(1-(cv_c/cv_t)^2T^{-1})$ where $cv_c$ and $cv_t$ are the critical values at the chosen significance level. Equally, since $q^2$ is $R^2/1-R^2$ where $R^2$ is the population $R^2$ with $\beta=0$, then the coefficient test will have larger non-centrality parameter than the $t$-ratio test if $R^2>1-[T(1+\beta)^2]^{-1}$ (e.g. if $\beta=-0.01$ and $T=100$, then the cut-off point will be such that $R^2>0.497$). Finally, note that for $q>0$, the non-centrality parameter of $\bar{t}_E$ is larger than that of $\bar{t}_{co}$, while the variance of the $\hat{T}_\beta_{co}$ is larger than that of $\hat{T}_\beta_{E}$.

5. FINITE SAMPLE EVIDENCE

To examine the size and power of the C-O and ECM statistics in finite samples, a set of Monte-Carlo experiments were conducted with (1) and (2) as the DGP, using simulations based on 25,000
replications generated in GAUSS386. A single exogenous regressor, \( k=1 \), was used for illustrative purposes. Data were generated with the normalization \( \sigma_e = 1 \), without loss of generality, leaving three parameters \((s, \alpha, \beta)\) and the sample size \( T \) as experimental design variables. In this study we choose

\[
\begin{align*}
  s &= (0.05, 1, 5, 20) \\
  \alpha &= (0.1, 0.9) \\
  \beta &= \begin{cases} 
  0 \ [\text{no cointegration}], & -0.05, -0.10 \ [\text{cointegration in both cases}] 
\end{cases} \\
  T &= (100)
\end{align*}
\]

The implied range of the "signal-to-noise" ratio is broad, including values potentially favourable and unfavourable for the relative power comparisons among the different tests. In order to simplify the analysis, under the alternative hypothesis, the value of the cointegrating slope, \( \lambda \), was fixed equal to 1. Similarly, the values of the short-run elasticity, \( \alpha \), attempt to capture a smaller (\( \alpha=0.1 \)) and a similar value (\( \alpha=0.9 \)) relative to the one chosen for \( \lambda \). Combining the values of \( \alpha \) and \( \lambda \) with those for \( s \), we obtain a wide range of values for \( q \), ranging from 0.005 to 18.

In order to compute the non-linear estimators in the C-O procedure, we have followed Hansen's advice in using a bias adjusted estimator of \( \beta \) in the initial iteration. Thus, if \( \hat{\beta}_{co}^1 \) is the estimator in the initial iteration, let us define

\[
\hat{\beta}_{co}^* = \hat{\beta}_{co}^1 + a/T
\]

where \( a > 0 \) is a fixed constant which Hansen suggests selecting
equal to 10. Eight iterations were performed with this procedure and, at the final stage, a/T was subtracted from $\hat{\beta}_H^*$, in order to use the standard Dickey-Fuller tables.

Finally, in order to enlarge the range of the comparisons, we have also included the well known Engle and Granger (1987) test (henceforth denoted as EG test), based of the static regression model. This test suffers both from the "curse of dimensionality" and the "common-factor restriction" problem (c.f. Phillips and Ouliaris (1990) and Kremers et al. (1992)), so that it is useful to see how it performs relative to the other tests discussed in this paper.

Under the null of no cointegration ($\beta=0$) Table 1 presents a summary of the critical values at both tails of the distributions. In order to afford comparisons with the standard Dickey-Fuller distribution, to which the C-O test should correspond under the null, the first row in Table 1 offers the cumulative distribution of the DF test (c.f. Fuller (1976)). The empirical distributions were computed under the different choices of $s$, turning out to be highly invariant to the chosen value of that ratio, in agreement with analytical results contained in Proposition 1. Given this degree of invariance, the reported figures correspond to the averages of the critical values across the chosen range of values for $s$. On the one hand, it can be observed that the empirical distribution of the C-O test is close to the DF unit root distribution, although there seems to be more divergence in the case of the coefficient version than in the t-ratio version of the tests, where the deviations seem to be small. On the other hand, as expected, the empirical distribution of the ECM differs from the unit root distribution, reflecting the fact that it is not
dimension-free. Similarly, the EG test, being a residual based test, also differs from the standard DF distribution.

Next, in order to examine the dependence of the test on the dimension of the system, we compare, in Table 2, the evolution of the critical values as the number of regressor is extended from one, as before, to five exogenous variables when T=100. The results here confirm our earlier finding. The t-tests seem to be more immune to the "curse of dimensionality" than the coefficient tests and, as expected, the ECM and EG tests shift to the left in distribution as the dimension of the system increases.

Finally, Table 3 reports size adjusted powers for the selected range of values for $\alpha$ and s, when $\beta=-0.05$ and $\beta=-0.10$. Since only negative values are consistent with the stability of the system, a one-sided 5% test was used. The results seem to be consistent with the asymptotic results derived in the previous section. First, when $q$ is low and $c$ is small, e.g. $c=-5$ when $\beta=-0.05$ and $T=100$, the ECM test, both in its t-ratio and coefficient versions, seems to be slightly less powerful than the C-O test, reflecting the "curse of dimensionality". However, as $q$ increases, either because $\alpha$ becomes different from $\lambda$ or because $s$ rises, the ECM test becomes the most powerful. Also, in agreement with the degeneration of the asymptotic distributions of the coefficient version of the tests, their absolute power decreases as $q$ increases. This is clearly not the case with the t-ratio versions where the ECM tests shifts its complete distribution to the left so as to achieve maximum power. For example, an extreme case is when $c=-5$ ($\beta=-0.05$), $\alpha=0.1$ and $s=20$, where the t-ratio version of the ECM test rejects 100% of the time, the C-O test almost does not reject at all.
As regards the power of the EG test, the results indicate that its power also decreases as \( q \) increases, though at a lower rate than the power of the C-O test. In agreement with the results in Banerjee et al. (1986), it turns out to have lower power than the ECM test, even when \( q \) is small.

5. GENERALISATIONS

The common factor problem of the C-O statistic remains when (1) includes additional lags. Furthermore, the use of the ADF test-statistic, or the non-parametric corrections suggested by Phillips (1987a), on the C-O residuals do not resolve the problem. Since this argument is similar to that given by Kremers et al. (1992) where the potential cointegration vector is assumed to be known a priori, we will not discuss it further. However, we note a few issues. First, if (1) is generalized to

\[
\gamma(L)\Delta y_t = \alpha(L)'\Delta x_t + \beta(y - \lambda' x)_{t-1} + \epsilon_t
\]

then \( e_t \) in the C-O procedure given by

\[
e_t = (\alpha(L) - \gamma(L)\lambda')'u_t + \epsilon_t
\]

need not be white noise. Indeed, in general, it will follow a moving average (MA) process, which are accounted by means of the Phillips and Perron's (1988) \( Z \) statistics. It is known than when the roots of such MA processes are close to be on the unit circle, these tests may suffer from severe size distortions; (c.f. Schwert (1989)).

Second, the simplifying assumption that \( u_t \) is white noise in
(1) can be replaced by being $I(0)$, but long-run independent of $\epsilon_t$, that is $B^\epsilon_u$ will still be an independent Brownian motion of $B^\epsilon_e$, with long-run variance (for $k=1$) given by:

$$\omega^2 = \sigma^2_u + 2\phi_u$$

where $\sigma^2_u = E(u_t^2)$ and $\phi_u = \sum_{j=2}^{\infty} E(u_t u_{t+j})$. In this case, the limiting distributions in Proposition remain similar, except that the "signal-to-noise" ratio $q$ now becomes

$$q = (\alpha-\lambda)\omega_u/\sigma^2_{\epsilon_e}$$

Third, there is the more realistic case where $x_t$ is not strongly exogenous, as assumed in DGP(1)-(2), but only weakly exogenous for the parameters of interest $\psi=(\beta,\lambda')'$, in the Engle et al. (1983) sense. In this case, the more general DGP will consist of (1) and the following marginal process for $\Delta x_t$.

$$\Delta x_t = u_t = \sum_{j=0}^{\infty} A_j a_{t-j}, \sum_{j=0}^{\infty} ||A_j|| < \infty$$

(2')

where the $(k+1)$ innovation vector $a_t=(\epsilon_{t-1}, \eta_t')'$ is assumed to be a strictly stationary and ergodic with zero mean and finite covariance matrix $\Sigma_a=\text{diag}(\sigma^2_{\epsilon}, \Sigma_{\eta})>0$. Thus, in this more general case, the partial sum process constructed form the $(k+1)$ vector $v_t=(\epsilon_t, u_t')'$ will now converge to BM$(\Omega)$ where
\[ \Omega = \begin{pmatrix} \omega_{\varepsilon \varepsilon} & \omega_{uv} \\ \omega_{ue} & \Omega_{uu} \end{pmatrix} = \Sigma + \Lambda + \Lambda' = \Delta + \Delta'; \quad \Sigma = \begin{pmatrix} \sigma_{\varepsilon}^2 & 0' \\ 0 & \Sigma_{uu} \end{pmatrix} \]

with \[ \omega_{\varepsilon \varepsilon} = \sigma_{\varepsilon}^2, \quad \omega_{ue} = \sum_{j} E(u_j \varepsilon_t) \quad \text{and} \quad \Lambda = \sum_{j} E(v_j v'_t). \]

Let \[ I_t = \sigma(a_t, a_{t-1}, \ldots). \] Then, since \( E(\varepsilon_t I_t) = 0 \), OLS will yield efficient estimates of \( \beta \) in \((1')\) and the ECM tests can be implemented in a single equation framework, yielding limiting distributions as those obtained in Proposition 2.

Notice that this follows because, under the previous assumptions, the correlation between \( \varepsilon_t \) and present and lagged values of \( \Delta x_t \) is zero, i.e. \( \Delta x \sum_{j} E(u_j \varepsilon_t) = 0 \). Thus, second-order bias effects capturing the "one-sided long-run covariance" will be absent in the limiting distributions of the ECM test-statistics, as in Proposition 2. However, note that in this case, \( B_{\varepsilon} \) and \( B_u \) are no longer independent Brownian motions. To illustrate that feature take the following simple example. For \( k=1 \), let

\[ \Delta x_t = \gamma \Delta y_{t-1} + \eta_t = \gamma(\omega_{t-1} + \varepsilon_{t-1}) \eta_t \] with \( E(\varepsilon_t \eta_t) = 0 \) for all \( t \) and \( s \), then \( x_t \) will be weakly exogenous for \( \psi \) in \((1')\), but the long-run covariance between \( B_{\varepsilon} \) and \( B_u \) will be \( \gamma(1-\omega_1)^{-1} \sigma_{\varepsilon}^2 \) under the null hypothesis of non-cointegration. This is so since \( \sum_{j} E((\varepsilon_0 u_t) = 0, \)

implying that the limiting distributions obtained in Proposition 2, will now depend on nuisance parameters \( (\omega_{ue}) \) and the corresponding tests will not be asymptotically similar. Thus, in principle, the computation of critical values in this more general case is problematic. Consequently, the appropriate critical values
will differ from those tabulated in Table 1 where \( B_c \) and \( B_u \) were assumed to be BM(I).

To overcome the problem of lack of similarity, we follow in part the seminal work of Hansen and Phillips (1990) on the derivation of ''modified'' estimators which, under cointegration, achieve mixed Gaussian asymptotic distribution. Since our work is under the null of non-cointegration, the idea here is slightly different, namely to reformulate functionals of Brownian motions \( B(r) = BM(\Omega) \) into distributionally equivalent functionals of independent standard Brownian motions \( BM(I) \), which will now be denoted as \( W(r) \). The mapping between the unstandardised \( B(r) \) and the standardised \( W(r) \) is given by \( W(r) = K'B(r) \) where \( \Omega^{-1} = KK' \); c.f. Phillips and Ouliaris (1990). Then

\[
K' = \begin{bmatrix}
\Omega^{-1/2} & \Omega^{-1/2} & \Omega^{-1} \\
\omega_{cc} & \omega_{cu} & \omega_{u} \\
\omega_{ec} & \omega_{cu} & \omega_{u} \\
0 & \Omega^{-1/2} & 0 \\
0 & \Omega^{-1/2} & 0 \\
\end{bmatrix} = \begin{bmatrix}
h & -hd' \\
0 & \Omega^{-1/2} \\
\end{bmatrix}
\]

with \( \omega_{cc} = \omega_{ee} - \omega_{ec} \Omega^{-1} \omega_{u} \omega_{u} \omega_{ec} \), \( \omega_{ee} = \sigma^2 \) and \( d' = \omega_{cu} \Omega^{-1} \omega_{u} \). Thus, \( W = h(B - d'B) \) and \( W = \Omega^{-1/2}B \).

Let \( \Delta y_t^* = \Delta y_t - d' \Delta x_t \) where \( d = \Omega^{-1} \omega_{u} \omega_{u} \). Note that, using residuals from the NLS estimation of \( (1') \) we can estimate \( \Omega_u, \omega_{ue} \) and \( h^{-1} \) consistently by

\[
\hat{\Omega}_{uu} = T^{-1} \sum_{t=1}^{T} \Delta x_t \Delta x_t' \\
\hat{\omega}_{ue} = \sum_{i=1}^{1} \tilde{\gamma}_i; \quad \tilde{\gamma}_i = T^{-1} \sum_{t=1}^{T} \Delta x_t \tilde{\varepsilon}_{t-1} \\
\hat{\omega}_{ue} = \sum_{i=1}^{1} \tilde{\gamma}_i; \quad \tilde{\gamma}_i = T^{-1} \sum_{t=1}^{T} \Delta x_t \tilde{\varepsilon}_{t-1}
\]
\[ h^{-1} = \tilde{\omega}^{1/2} = \left( \sigma_e - \bar{u} \bar{u} \bar{\omega} \right)^{1/2} \]

where the weights \( \tilde{\omega} \) are usually selected so that for each \( i \), \( T^{\tilde{\omega}} \) as \( T^{\omega} \) so that \( l=0(T^{1/4}) \); c.f. Newey and West (1987). One simple choice for the weights is the Bartlett window \( \tilde{\omega} = 1- |l|/(1+1) \) with \( l=\text{int}(1+5T^{-7/4}) \) as suggested by Bierens (1993). Then, the following result holds:

Proposition 6. For DGP (1)-(2'), under the null hypothesis (\( \beta=0 \)), the ECM modified estimator and its t-ratio (denoted as \( \beta_{\text{ME}} \) are defined as

\[ \hat{\beta}_{\text{ME}} = [y' M y]^{-1} y' M \Delta y' \]

\[ t_{\text{ME}} = [\tilde{\omega}^{-1} y' M y]^{1/2} \hat{\beta}_{\text{ME}} \]

and have the following limiting distributions

\[ T_{\text{ME}} \Rightarrow [\tilde{W}_e]^{-1} \tilde{W}_e dW_e \]

\[ t_{\text{ME}} \Rightarrow [\tilde{W}_e]^{-1/2} \tilde{W}_e dW_e \]

with \( \tilde{W}_e = W - (W W')' (W W')^{-1} W \).

Thus, form the previous result we can observe that the modified estimator \( \hat{\beta}_{\text{ME}} \) can be interpreted as the OLS estimator of the coefficient on \( y_{t-1} \) in the regression of \( \Delta y_t' \) on \( \Delta x_t \) and \( \Delta y_{t-1} \).

Note that \( \Delta x_t \) is excluded from the set of regressors, since in that case the use of the projection matrix \( M \) in the partitioned regression would imply \( M \Delta y = M \Delta y \) given that \( M \Delta x = 0 \).
Finally, though deterministic terms have been ignored in the previous analysis for the sake of simplicity, the data may be demeaned, or demeaned and detrended, before applying the various tests for cointegration. The limiting distributions of the various tests discussed in the paper in such cases are of the same form, except that the Brownian motions are replaced by the appropriate Brownian bridges. The asymptotic critical values for the ECM test in its t-ratio version, which are only available for $k=1$ (Banerjee et al. (1993)) are extended in Table 4. In order to analyse the finite sample distribution of those tests the critical values for the lower tail of the distribution in Table 4 up to five regressors for four different sample sizes ($T=25, 50, 100$ and $500$) are also presented. Since there are many examples in applied work of single equation conditional models with weakly exogenous regressors for the parameters of interest (see, e.g. Hendry, 1987), we think that the above critical values may be widely applicable.

6. CONCLUSIONS

Testing for cointegration has become an important facet of empirical analysis of economic time series over the last several years and various tests are being used. In this paper, we compare the relative performance of dimension-invariant tests whose distributional theory does not depend upon the dimensionality of the system but impose common-factor restrictions and tests which are not dimension-free but do not impose such restrictions. Using the argument of Kremers et al. (1992), we show that in realistic cases the former may have poor power properties. Moreover, as a byproduct of the analysis, we show that, in spite of coefficient
tests being $O_p(T)$ and t-ratio tests being $O_p(T^{1/2})$ under the alternative hypothesis of cointegration, the latter may have better power properties. The results are obtained for a simple DGP and then shown to extend to more general cases.

NOTES

1. However, if $\alpha=\lambda$ in the DGP, then the non-centrality parameters of the EDF and C-O tests are identical since now $\hat{\lambda}_E$ is a consistent estimate of $\lambda$.

2. The following example taken from Gregory and Hansen (1993) serves as an illustration of the previous result. In their Table 2, they generate simulations of the DGP, $y_t=1+2x_t+\epsilon_t$ and $x_t=y_t+\eta_t$ with $\epsilon_t=(1-\rho L)^{-1}v_t$ and $\Delta \eta_t=\omega_t$ where $\omega_t$ and $v_t$ are orthogonal nid$(0,1)$ processes. The critical values at 5% level of the $Z_\alpha$ (coefficient) and $Z_t$ (t-ratio) tests (with constant term) are $-40.48$ and $-4.61$ respectively. Using the asymptotic distributions for $T_\beta$ and $t_\alpha$ in Proposition 5, for $\beta=-0.5$ and $T=50$, the rejection probabilities are $Pr(\phi<0.30)$ (t-ratio test) and $Pr(\phi<-2.53)$ (coefficient test) where $\phi$ is a standardised normal variate. Similarly for $\beta=-1$, they are $Pr(\phi<2.46)$ and $Pr(\phi<1.35)$ respectively. Thus, the results in Proposition 5 provide a simple explanation of their finding that the $Z_t$ test has better power properties than the $Z_\alpha$ test in those instances.
REFERENCES

APPENDIX

The analysis contained in this appendix draws on a number of well known results in Phillips (1987b, 1988) and Phillips and Ouliaris (1990). Under the null hypothesis of no-cointegration, the DGP \( H_0 \) is given by

\[
\Delta y_t = \alpha' \Delta x_t + \varepsilon_t; \quad \begin{pmatrix} \varepsilon_t \\ u_t \end{pmatrix} \sim \text{IN} \begin{pmatrix} 0 \\ 0 \\
\sigma_e^2 \\ \Sigma_u \end{pmatrix}
\]

\[
\Delta x_t = u_t;
\]

The results do not depend on the initialization, so let us define

\[
S_{ct} = \sum_{t=1}^{T} \varepsilon_t \quad \text{and} \quad S_{ut} = \sum_{t=1}^{T} u_t
\]

and let \( S_{\varepsilon} \) and \( S_{u} \) be \((T \times 1)\) and \((T \times k)\) matrices of observations on \( S_{ct} \) and \( S_{ut} \), respectively. Note that \( x = S_u \) and \( y = S_\alpha + S_\varepsilon \). Let \( M_1 \) be the projection matrix

\[
M_1 = I - x_{-1} (x'_{-1} x_{-1})^{-1} x'_{-1}
\]

Then, the following set of asymptotic results (R1) are used in the proofs:

(a) \( T^{-1} S'_{\varepsilon} M_1 S_{\varepsilon-1} \varepsilon-1 \rightarrow \sigma_{\varepsilon}^2 \tilde{\Sigma}_{\varepsilon} \)

(b) \( T^{-1} S'_{\varepsilon} M_1 \varepsilon \rightarrow \sigma_{\varepsilon}^2 \tilde{B}_{\varepsilon} d\varepsilon \)

(c) \( T^{-1} u' M_1 u = o_p (1) \)

(d) \( T^{-1} S'_{\varepsilon} M_1 u = o_p (1) \)

(e) \( T^{-1} \sum_{t=1}^{T} \varepsilon_t u_t = o_p (1) \)

where \( \tilde{B}_{\varepsilon} = B_{\varepsilon} - (J B_{\varepsilon} B_{\varepsilon}') (J B_{\varepsilon} B_{\varepsilon}')^{-1} B_{\varepsilon} \).

Under the local alternative hypothesis of near-no cointegration the DGP \( H_{1a} \) is given by
\[ \Delta z_t = \beta z_{t-1} + e_t \]
\[ \Delta x_t = u_t \]

with \( \beta = -c/T \); \( z_t = y_t - \lambda' x_t \), \( e_t = (\alpha - \lambda)' u_t + c_t \) and \( z \) and \( e \) are \((T \times 1)\) vectors of observations on \( z_t \) and \( e_t \).

In this case the following additional asymptotic results \((R2)\)

are used

(a) \[ T^{-2} z' z \Rightarrow \sigma_e^2 \int K_e^2 \]

(b) \[ T^{-2} z' M_{11} z \Rightarrow \sigma_e^2 \int K_e^2 \]

(c) \[ T^{-2} z' M_{11} \varepsilon \Rightarrow \sigma_e \sigma \int K_e \Delta B \]

(d) \[ T^{-1} z' \varepsilon \Rightarrow \sigma_e^2 \int K_e dB \]

(e) \[ T^{-2} x' z \Rightarrow \sigma_e \Sigma^{1/2} J B K_{u \varepsilon} \]

where \( \tilde{K}_{e \varepsilon} = K - (J B K) (J B B')^{-1} B_{u \varepsilon} \)

and

\[ \sigma_e^2 \int K_e^2 = (\alpha - \lambda)' \Sigma^{1/2} (J K K') \Sigma^{1/2} (\alpha - \lambda) + 2(\alpha - \lambda)' \sigma \Sigma^{1/2} J K K + \sigma^2 \int K_e^2 \]

Proof of Proposition i

See Hansen (1990, Theorem 2)
Proof of Proposition 2

Let \( V \) be a \((T \times 2k)\) matrix of observations on \( v_t = (\Delta x'_t, x'_t) \) and \( x_{-1} \) and \( \Delta x \) be \((T \times k)\) matrices of observations on \( \Delta x_t \) and \( x_{t-1} \), respectively. Define the projection matrices \( M = I - V'(V'V)V' \) such that, by partitioned inverses, \( M = M_1 M_1 \Delta x (\Delta x' M_1 \Delta x)^{-1} \Delta x' M_1 \).

Then, \( \hat{\beta}_e \) is computed such that

\[
T \hat{\beta}_e = (T^{-2} y'_{-1} M y_{-1})^{-1} (T^{-1} y'_{-1} M \Delta y)
\]

\[
= (T^{-2} S' \varepsilon_{-1} M S \varepsilon_{-1})^{-1} (T^{-1} S' \varepsilon_{-1} M \varepsilon)
\]

since \( y = S_u \alpha + S_e \varepsilon \), \( \Delta y = u \alpha + \varepsilon \) and \( M \) is orthogonal to \( x_{-1} \) and \( \Delta x \). Using parts (a) to (d) of (R1) and the relationship between \( M \) and \( M_1 \) we have

\[
T^{-2} S' \varepsilon_{-1} M S \varepsilon_{-1} = (T^{-2} S' \varepsilon_{-1} M S \varepsilon_{-1}) - T^{-1} (T^{-1} S' \varepsilon_{-1} M u)(T^{-1} u'M u)^{-1} (T^{-1} u'M \varepsilon)
\]

\[
= T^{-2} S' \varepsilon_{-1} M S + T^{-1} 0 (1) 0 (1) 0 (1) = T^{-2} S' \varepsilon_{-1} M S \varepsilon - T^{-1} 0 (1) 0 (1) = T^{-2} S' \varepsilon_{-1} M S \varepsilon + o (1)
\]

and

\[
T^{-1} S' \varepsilon_{-1} M \varepsilon = (T^{-1} S' \varepsilon_{-1} M \varepsilon) - (T^{-1} S' \varepsilon_{-1} M u)(T^{-1} u'M u)^{-1} (T^{-1} u'M \varepsilon) =
\]

\[
T^{-1} S' \varepsilon_{-1} M \varepsilon - T^{-1} 0 (1) 0 (1) 0 (1) = T^{-1} S' \varepsilon_{-1} M \varepsilon + o (1)
\]

since \( T^{-1} u'M \varepsilon = (T^{-1} u' \varepsilon) - T^{-1} (T^{-1} u' x_{-1})(T^{-2} x' x_{-1})^{-1} (T^{-1} x' \varepsilon) = o (1) \), given (e) in R(1).

Next, using the limiting distributions in (a) and (b) in R(1), yields the required results.
\[ T_E = (S' M S_{-1} S' M e_1) + o(1) = (J B E_{-1} J B E e_1 e_1) \]

To prove that \( \hat{\sigma}_e \rightarrow \sigma_e \), just write

\[ \hat{\sigma}_e^2 = T^{-1} e_1 e_1 M e_{-1} = T^{-1} e_1 e_1 - T^{-1}(I^{-1} e_1 P)(I^{-2} P' P)^{-1}(I^{-1} P' e_1) \]

\[ = T^{-1} e_1 e_1 - T^{-1} (1) 0 (1) 0 (1) = \sigma_e^2 + o(1) \]

where \( P \) is the \((T \times 2k+1)\) matrix of observations on \((\Delta x_t', x_{t-1}', y_{t-1}')\)
and \( M = I - P(P' P)^{-1} P' \).

From (A.1) and (A.2) the distribution of the \( t \)-ratio follows along the same lines, leading to the required results.

**Proof of Proposition 3**

Define \( z_t = y_t - \lambda x_t' \), \( \hat{z}_e = y_t - \hat{\alpha} x_t' \) and \( \hat{z}_t = y_t - \hat{\alpha}_x x_t' \).

Then

\[ z_t = \hat{z}_t + (\lambda - \lambda) x_t' = \hat{z}_t (\alpha - \lambda)' x_t' + o(1) \]

and

\[ z_t = \hat{z}_t + (\hat{\alpha}_x - \lambda) x_t' = \hat{z}_t (\alpha - \lambda)' x_t' + o(1) \]

since \( \lambda \rightarrow \infty \) and \( \hat{\alpha}_x \rightarrow \alpha \) at rate \( o(T^{-1/2}) \). Let \( \tilde{z}_t = z_t -(\alpha - \lambda)' x_t' \) and \( \tilde{z} \) is the \((T \times 1)\) vector of observations on \( \tilde{z}_t \).

Then, from (A.3) and (A.4), the C-O and ECM estimators can be written as
\[
\hat{T}_\beta_{c_0} = (T^{-2}z'_{c_0-1}z_{c_0-1})^{-1}(T^{-1}z'_{c_0-1}\Delta z_{c_0-1}) = \\
T\beta_+ (T^{-2}z'_{-1}z_{-1})^{-1}T^{-1}z'_{-1}(e+\beta x_{-1}(\alpha-\lambda)) + o_p(1) \tag{A.5}
\]

and

\[
\hat{T}_\beta_{e} = (T^{-2}y'_{-1}My_{-1}) (T^{-1}y'_{-1}M\Delta y) = (T^{-2}z'_{-1}Mz_{-1})^{-1}(T^{-1}z'_{-1}M\Delta y) \\
= T\beta_+ (T^{-2}z'_{-1}Mz_{-1})^{-1}(T^{-1}z'_{-1}M_1\varepsilon) + o_p(1) \tag{A.6}
\]

since \(M\) is orthogonal to \(x_{-1}\) and \(\Delta x\) and the limiting distribution of \((T^{-2}z'_{-1}Mz_{-1})\) is equal to the limiting distribution of \((T^{-2}z'_{-1}M_1z_{-1})\), as shown in the proof of Proposition 2.

Then using \(T\beta = -c\) and substituting results (a) to (e) in (R2) into (A.5) and (A.6) yields the required results. Since \(\hat{\sigma}_e \to \sigma_e\) and \(\hat{\sigma}_e \to \sigma_e\), the proofs for the t-ratio statistics follow along similar lines, leading to the required results. \(\blacksquare\)

Proof of Proposition 4

For \(k=1\), from the limiting distributions in Proposition 3, we have

\[
\hat{T}_\beta_{c_0} \to (f\hat{B}_e^2)^{-1}[-c JK_{e e}\hat{B}_e + (\sigma / \sigma_e) f\hat{B}_e dB_e] 
\]

where \(\hat{B}_e = [K_{e e}-(\alpha-\lambda)'(\sigma / \sigma_e)]B_e\).

Since \(q = (\alpha-\lambda)\sigma_u / \sigma_e\), it follows that \((\sigma / \sigma_e) = (1+q^2)^{-1/2}\) and \((\alpha-\lambda)\sigma_u / \sigma_e = q / (1+q^2)^{1/2}\). Thus, as \(q \to 0\), \((\sigma / \sigma_e) \to 0\) and
\[(\alpha - \lambda)(\sigma / \sigma_e)^+1, \text{ i.e. } \hat{\beta}_e \equiv K_e, \text{ implying the required result for } \hat{\beta}_{e_0},\]

namely

\[
\hat{\beta}_{e_0} \rightarrow -c\hat{f}(K^2 - K B_e) / \sqrt{f(K - B_e)^2 + o(q^{-1})}
\]

As regards \(\hat{\beta}_e\), we have

\[
\hat{\beta}_e \rightarrow -c + (\sigma / \sigma_e)(\hat{f}B_e^2)^{-1}(\hat{f}B_e dB_e)
\]

where \(\hat{B}_e = K_e - (\hat{f}B K_e)(\hat{f}B_e^2)^{-1}B_e\). Since \((\sigma / \sigma_e) = (1 + q^2)^{-1/2}\), as \(q \uparrow \infty\)

\((\sigma / \sigma_e)^+ \rightarrow 0\) and

\[
\hat{\beta}_e \rightarrow -c + o(q^{-1})
\]

as required. Since \(\hat{\sigma}_e \rightarrow \sigma_e\) and \(\hat{\sigma}_e \rightarrow \sigma_e\) the proofs for the limiting distribution t-ratios proceed along similar lines. \(\blacksquare\)

Proof of Proposition 5

Under a fixed alternative, the DGP(\(H_a\)) is given by

\[
\Delta y_t = \alpha' \Delta x_t + \beta(y_{t-1} - \lambda' x_{t-1}) + \epsilon_t
\]

\[
\Delta x_t = u_t
\]

with \(\beta < 0\). Then, \(z_t = y_t - \lambda' x_t\) is governed by the following AR(1) process

\[
z_t = [1 - (1 + \beta)L]^{-1}[(\alpha - \lambda)'u_t + \epsilon_t] = [1 - (1 + \beta)L]^{-1}e_t
\]

where \(L\) is the lag operator and the variance of \(z_t\) is \(V(z_t) = \sigma_e^2[1 - (1 + \beta)^2]^{-1}\).

Then,
\[ T^{1/2}(\hat{\beta}_{co} - \beta) = (T^{-1}z'z)_{-1-1}^{-1}T^{-1/2}z'_1 \Delta z + o_p(1) \Rightarrow N[0, 1-(1+\beta)^2] \]

by standard theory (e.g. Anderson, 1971, Chapter 5).

Thus,

\[ T\hat{\beta}_{co} = T(\hat{\beta}_{co} - \beta) + T\beta = T^{1/2}N[0, 1-(1+\beta)^2] + T\beta = O_p(T) \]

and

\[ t_{co} = (T^{-1}\sum_{e} z'_e z_e)_{-1-1}^{1/2}[T^{1/2}(\hat{\beta}_{co} - \beta) + T^{1/2}\beta] \Rightarrow N(0, 1) + [T/1-(1+\beta)^2]^{1/2}\beta \]
\[ = O_p(T^{1/2}) \]

Similarly,

\[ T^{1/2}(\hat{\beta}_{E} - \beta) \Rightarrow N[0, \sigma_e^2[1-(1+\beta)^2]/\sigma_e^2] = N[0, (1-(1+\beta)^2)/1+q^2] \]

where \( q^2 = \sum (\alpha - \lambda)' \sum (\alpha - \lambda)/\sigma_e^2. \)

Thus,

\[ T\hat{\beta}_{E} = T^{1/2}N[0, (1-(1+\beta)^2)/1+q^2] + T\beta = O_p(T) \]

and

\[ t_{E} = (T^{-1}\sum_{E} z'_E z_E)_{-1-1}^{-1/2}[T^{1/2}(\hat{\beta}_{E} - \beta) + T^{1/2}\beta] \Rightarrow N[0, 1] + [T(1+q^2)/(1-(1+\beta)^2)]^{1/2} = O_p(T^{1/2}) \]

as required.\*
Proof of Proposition 6

Let

\[ \tilde{W}_1 = W_1 - (\sum_{1} W_1 \cdot (\sum_{1} W_1)\cdot(\sum_{1} W_1)^{-1} \cdot W_1 \cdot (\sum_{1} W_1)^{-1} \cdot W_1 \cdot (\sum_{1} W_1)^{-1} \cdot W_1 \]

\[ \tilde{B}_c = B_u - (\sum_{u} B_u \cdot (\sum_{u} B_u)\cdot(\sum_{u} B_u)^{-1} \cdot B_u \cdot (\sum_{u} B_u)^{-1} \cdot B_u \cdot (\sum_{u} B_u)^{-1} \cdot B_u \]

Then, since \( W_1 = h(B_c - d' B_u) \) and \( W_2 = \Omega_{uu}^{-1/2} B_u \), it follows that

\[ \tilde{W}_1 = h \tilde{B}_c \]

Therefore,

\[ \sum_{1} W_1^{-2} = h^2 \sum_{1} B_c^2 \]

and

\[ \sum_{1} W_1 dW_1 = h^2 \sum_{1} B_c dB_c - h^2 d' \sum_{1} B_c dB_u \]

Hence,

\[ ([\sum_{1} W_1^{-2}]^{-1} [\sum_{1} W_1 dW_1] = ([\sum_{1} B_c^2]^{-1} [\sum_{1} B_c dB_c - d' \sum_{1} B_c dB_u]) \quad (A.7) \]

Therefore, the "modified" ECM estimator defined by

\[ T_{\beta_{EM}} = [T^{-2} \gamma_1' M_1' \gamma_1] [T^{-1} \gamma_1' M_1 (\Delta y - \Delta x)] \]

has the limiting distribution given in (A.7) since

(i) \( \hat{d} \to d \)

36
(11) \( T^{-2} y' M_1 y \sim \sigma^2 \int B^2 \) and \( T^{-1} y' M_1 \Delta y \sim \sigma^2 \int_\epsilon^2 d\epsilon \)

(as shown in Proposition 1)

(iii) \( T^{-1} y' M_1 \Delta x = T^{-1} y' M_1 u = T^{-1} S M_1 u = \int B dB \) (by (d) in R1)

leading to the required results. The proof for the "modified" ratio \( t_{\text{ME}} \) follows along similar lines. \( \blacksquare \)
Table 1

Critical Values for the Coefficient (t-ratio) Version of the Tests

Size (k=1)

<table>
<thead>
